Accurate simulation of seismic wave propagation in complex geological structures is widely used for environmental and industrial applications for subsurface structure evaluation and in seismic exploration as a core tool of seismic imaging and inversion methods. However, conventional methods fail to simulate realistic wavefields in geological media with large and rapid structural changes, due to the presence of shadow zones, diffractions and/or edge effects. Different methods have been developed to improve seismic modeling in complex geological environment. They are typically tested either on synthetic configurations against “validated” methods, or via direct comparison with real data acquired in situ. Such approaches have limitations, especially if the propagation occurs in a complex environment with strong-contrast reflectors and surface irregularities. An alternative approach for seismics consists in comparing the synthetic data with data obtained in laboratory under controlled conditions for a known configuration. We present here a comparison of laboratory data of 2D and 3D zero-offset wave reflection from a strong topographic environment immersed in a water tank with synthetic data computed by means of a Spectral-Element Method and the Tip-Wave Superposition Method. The results indicate a good fit in time arrivals and amplitudes.

1 Introduction

Accurate simulation of seismic wave propagation in complex geological structures is widely used for environmental and industrial applications for subsurface structure evaluation and in seismic exploration as a core tool of seismic imaging and inversion methods. In models with simple structures and slowly varying material properties, conventional methods (e.g., ray methods, finite-difference methods) are efficient tools. However, difficulties arise for complex geological structures with large and rapid structural changes, and conventional methods fail to simulate realistic wavefields, due essentially to the presence of shadow zones, diffractions, and edge effects. Different methods have thus been developed to improve seismic modeling in complex geological environments with structural complexities like faults with steep dips or curved reflectors. They are typically tested on synthetic configurations against analytical solutions for simple canonical problems or reference methods, and several projects focusing on verification and validation of numerical methods have been conducted in the last few years [11]. Such an approach has limitations, especially if the propagation occurs in a complex environment with strong-contrast reflectors and surface irregularities, as it can be difficult to determine the method which gives the best approximation of the “real” solution given by a reference method. Another approach is to validate these methods via direct comparison with real data acquired in situ [9]. Unfortunately, without a priori (good) knowledge of the geological environment, the interpretation of the obtained results may be a tedious task due to the existence of diffraction and sideswipe events.

An alternative approach for seismics consists in comparing the synthetic data with data obtained in the laboratory. In contrast with in situ experiments, high-quality data are collected under controlled conditions for a known configuration, which is crucial for comparisons with numerical models. Moreover, unlike synthetic data, laboratory data possess many of the characteristics of field data (random and signal-generated noise, multiples, mode conversions), as real waves propagate through models with no numerical approximations. Our aim is to study 3D complications in zero-offset reflection profiles acquired over a strong topographic environment in order to improve the understanding of the physical mechanisms involved in the interaction of the waves with irregular surfaces. As noted previously, in such a complex environment the numerical methods based on approximations may fail to simulate accurately the seismic wavefields and produce different results depending on their intrinsic hypotheses. The main purpose of this work is therefore to test the approach using laboratory data as reference data for benchmarking 2D and 3D numerical methods and techniques. Using the indoor tank facilities of the Laboratory of Mechanics and Acoustics (LMA, Marseille, France) we have performed laboratory-scaled measurements of zero-offset reflection of broadband pulses on a model containing topographic structures with several edges and corners and immersed in a water tank. The presence of these structures is expected to complicate the wavefields significantly. In what follows we present comparisons of these measurements with numerical data simulated by means of a Spectral-Element Method and a Discretized Kirchhoff Integral Method (DKIM).

2 Methods

2.1 Experimental method

We carried out laboratory experiments at Laboratory of Mechanics and Acoustics in Marseille, France. The model used in these experiments, called the “Marseille model”, is partly based on French model [7], but contains additional topographies such as a truncated dome and a truncated pyramid (Fig. 1(a)). The model of size 600 x 400 x 70 mm$^3$ is made of PVC material which is isotropic at ultrasonic frequencies, and whose measured properties are in the same range as those of typical geological media. The thickness of the model varies from 30 to 70 mm, the difference between two levels, separated by a planar fault, being 40 mm. The model was immersed in a water tank which is equipped with a computer-controlled system which allows for accurate positioning of the source and receiver. The measured properties of the materials are $V_p = 1476 - 1493$ m/s (depending on the water temperature), $\rho = 1000$ kg/m$^3$ in the water layer, and $V_p = 2220$ m/s, $V_s = 1050$ m/s, $\rho = 1412$ kg/m$^3$ in the PVC material. Attenuation in the PVC layer is described by quality factors $40 < Q_p < 60$ and $27 < Q_s < 31$ for P and S-waves, respectively. Attenuation in the water is negligible. As zero-offset seismic configuration is considered for these experiments, the model is illuminated by a piezoelectric transducer which operates both as a source and a receiver. Different kinds of transducers with a central frequency $f_c$ equal to 500 kHz are used: one transducer with diameter $D = 25.4$ mm and narrow-beam (NB) aperture (about 8° at −3 dB), and one transducer with diameter $D = 3$ mm and broad-beam (BB)
aperture (about $45^\circ$ at $-3$ dB), which allows us to obtain 3D zero-offset data.

Conventional ultrasonic pulse-echo technique was used to obtain the reflection data from the Marseille model. The distance from the transducer to the flat part of the model surface is either 105 mm $\pm$ 1 mm, or 150 mm $\pm$ 1 mm, the far-field condition being thus fulfilled for any position of the transducer. Wave propagation is performed in small-scale conditions, i.e., for instance, if a scale ratio of $2.10^4$ is considered an experimental frequency of 500 kHz corresponds to a real frequency of 25 Hz, and an experimental distance of 10 mm corresponds to a real distance of 200 m, velocities as well as densities and attenuations remaining unchanged.

We performed acquisitions along Y-lines with a spatial sampling $\Delta y$ equal to 2 mm (Fig. 1(b)). The collected data thus consist of numerous parallel profiles composed of a collection of reflection data for dense grids of source-receiver locations. We process reflection data to produce seismograms corresponding to different cross-sections of the model. We pay more attention to specific profiles because they present a high interest as they cross the main structures of the model. The data collected along these profiles might thus contain reflections and diffractions from all the structures. These profiles are represented by heavy-dashed lines in Fig. 1. The seismograms are obtained after application of a low-pass filter to raw data, in order to eliminate the harmonic resonances of the transducers. Additionally, for visualization purposes, we apply a clipping procedure with different clipping numbers $x$ to all seismograms presented below, i.e., saturation of all the signals whose amplitudes are greater than $x$ of the maximum amplitude, in order to enlighten weaker signals.

Fig. 2 shows seismograms corresponding to the acquisition line Y150 obtained with the NB and the BB transducers, respectively. Events with a time arrival smaller than 210 $\mu$s correspond to primary reflections from the top surface of the Marseille model, whereas events with greater time arrival correspond to either multiples, or reflections from the bottom surface. Noticeable discrepancies between data obtained with the two kinds of transducers can be identified in Fig. 2. More specifically, diffractions at the edges of the topographic structures can be clearly observed only on data obtained with the BB transducer. The steep slope of the fault however remains invisible whatever the transducer used. Additional experimental results obtained with both kinds of transducers can be found in [3, 5].

### 2.2 Numerical methods

We used two kinds of numerical methods for synthetic modeling of the zero-offset experiments: a Spectral-Element Method (SEM) and a Discretized Kirchhoff Integral Method (DKIM).

The SEM is based upon a high-order piecewise polynomial approximation of the weak formulation of the wave equation. It combines the accuracy of the pseudospectral method with the flexibility of the finite-element method [14]. In this method, the wave field is represented in terms of high-degree Lagrange interpolants, and integrals are computed based upon Gauss-Lobatto-Legendre quadrature. This combination leading to a perfectly diagonal mass matrix leads in turn to a fully explicit time scheme which lends itself very well to numerical simulations on parallel computers. It is particularly well suited to handling complex geometries and interface matching conditions [4]. The typical element size that is required to generate an accurate mesh is of the order of $\lambda$, $\lambda$ being the smallest wavelength of waves traveling in the model. Very distorted mesh elements can be accurately handled. The SEM may be computationally expensive depending on the size of the domain, especially for 3D domains and high-frequency simulations. We thus mesh the model in 2D with quadrangles using the open-source software package Gmsh [8]. We implement directional directivity of standard ultrasonic transducers using a set of equidistant omnidirectional sources (like a horizontal array) whose amplitude is weighted by a Hamming window. The radiation of the simulated source is directed along the vertical. It is obtained using 51 point sources distributed over a line length of 2.54 cm, which corresponds to the diameter of the NB transducer.

The DKIM is a method based on numerical evaluation of the Kirchhoff-Helmholtz surface integral, which is a powerful tool to model the scattered wavefield from a piecewise smooth interface [15]. Both the field and its normal derivative at the interface, appearing in the integral, are commonly computed using the Kirchhoff approximation,
Figure 2: Laboratory zero-offset data (seismograms) obtained with the narrow-beam transducer (a), and the broad-beam transducer (b). The transducer is located at 150 mm above the Marseille model. Clipping with $x = 15$ in (a) and $x = 40$ in (b) was applied.

Figure 3: Numerical simulations of the wave reflections, transmissions, and diffractions in the vicinity of the truncated dome using the 2D SEM.

In Fig. 5 we show the results of modeling of the primary reflection from the top of the PVC material using the DKIM, and more specifically the single-scattering seismograms for synthetic data along Line Y200, together with the total seismograms from laboratory data obtained with the BB transducer. Direct observation of the laboratory and single-scattering seismograms shows a good fit in the modeling of reflection and diffraction events. Note that for the case of the NB transducer, its focused beam cannot illuminate the out-of-plane structures which therefore are not observed on laboratory data. On the contrary, for the case of the BB transducer, diffractions at the edges of the topographic structures and reflections from the out-of-plane structures and the fault can be clearly observed in the synthetic data, in accordance with the experimental data, even if the acquisition line does not cross the top of the structures. Though the data are zero-offset, they exhibit interesting 3D effects. Nevertheless, the steep slopes of the truncated pyramid remain invisible.

In Fig. 6 we provide a more detailed qualitative comparison of the laboratory and synthetic traces, corresponding to three chosen source positions in Fig. 5. The top trace corresponds to the reflection from the slope of the out-of-plane full dome, the flat part of the model and the slope of the out-of-plane truncated dome. The middle
one corresponds to the reflections from the slope of the out-of-plane full dome and truncated dome, the flat part of the model and diffraction effects produced by the truncated part of the dome. The bottom one corresponds to diffraction effects produced by the fault, the reflection from the flat part of the model and diffraction effects produced by tips of the truncated pyramid. One can note a good fit of the traces in terms of shape and the phase of the signal, but discrepancies in terms of amplitude, since the traces contain diffractions and reflections from the out-of-plane structures.

We provide a more quantitative analysis by performing a numerical comparison of these three traces selected. We use several error norms for quantitative analysis of the misfit between the synthetic and laboratory data, namely the single-valued normalized cross-correlation coefficient \( cc \), the cross-correlation coefficient together with the root mean square (rms) misfit [6], and misfit criteria EM and PM based on the time-frequency representation using the continuous wavelet transform [10]. The single-valued normalized cross-correlation coefficient \( cc \) estimates the degree to which two signals are correlated in terms of phase and satisfies \(-1 \leq cc \leq 1\). The equality \( cc = 1 \) is for perfect correlation, \( cc = 0 \) for uncorrelated series, and \( cc = -1 \) for negative correlation.

We provide that comparison of the misfits between the three selected laboratory and numerical traces obtained with the BB transducer in Fig. 7. The qualitative results shown above are confirmed quantitatively by the high values of the normalized cross-correlation coefficient and the low values of PM on the one hand, indicating that the phase fit is good, and by relatively high values of the rms misfit on the other hand. However, the results indicate that there are phase shifts though the amplitude fit is good. The time shifts observed for the reflections from the slope of the fault are due to a possibly wrong tilt used for modeling.

4 Conclusion

We have tested an alternative approach for benchmarking numerical methods for 2D and 3D wave propagation. This approach consists in comparing synthetic data obtained using numerical modeling to laboratory data obtained for a known configuration. We have obtained the laboratory data by laboratory scale measurements of zero-offset reflection of broadband pulses, generated by narrow-beam and broad-beam sources, from a scaled representation of a geological model with strong 3D topographies immersed in water. The diffraction effects produced on the wavefields by the complicated features of the model, together with the existence of shadow zones, make the laboratory experiments under controlled conditions of interest. We have computed synthetic data by means of a spectral-element method and a discretized Kirchhoff integral method. The comparisons between synthetic and laboratory data exhibit a good

The data sets obtained during this measurement campaign seem promising for future use as a real-data benchmark for 2D and 3D model comparisons. The next step will consist in a multi-offset experiment with broad-beam transducer. In future work we plan to perform numerical cross-validation of 2D and 3D numerical methods and techniques on the obtained data in order to analyze the respective limitations of each method and to choose the right strategy for further development of the methods. This is the final goal of our project called BENCHIE (http://www.benchie.cnrs-mrs.fr/).
